Abstract
The purpose of the present study was to examine the effect of a walking exercise on body water in order to restore body water and reduction dehydration among sedentary obese and thin women. Forty young untrained girls between the age of 20-25 years (obese n=20, BMI>30 and thin n=20, BMI <20) volunteered to participate in this study. Participants were randomly assigned to two exercises (obese=10, thin=10) and two control (obese=10, thin=10) groups matched by BMI. DXA was used to measure each subject’s body water, percentage body fat and lean mass. Serum estrogen level by radioimmunoassay (RIA) was assessed. Each walking session was 30 min long at an intensity corresponding to 50-75% of maximal age adjusted heart rate, 3 days per week for 2 months. Percent body fat and lean mass were affected positively by exercise program and significant change was observed in Serum estrogen and body water in both exercise group (p<0.05-0.001). In conclusion this study demonstrated that 30 minutes walking exercise improved adaptation of body fluids and to exercise training in both obese and thin sedentary women.

Key words: walking exercise, body water, women, obese and thin

Introduction
During exercise, increased capillary hydrostatic pressure caused by elevation of arterial pressure produces plasma volume shifts from the vascular space to the interstitial fluids. Following a rapid efflux of vascular fluid within minutes of exercise, there is very little further reduction in plasma volume during exercise. Recall that body water content regulates sweating, and sweating provides our best method of heat loss during exercise. So, adequate body water is essential to avoid heat injury (e.g., heat exhaustion or heat stroke) (Convertino,1991). Body water retention is common in high estrogen states. There are a number of “fluid retention” hormones that exert a profound control over this fluid regulatory system. Hormones are substances in the body that act to promote certain activity by specific organs. The fluid regulatory hormones act primarily on the brain and kidney to control both intake and output of water. The most important hormone of this type is the antidiuretic hormone, which responds rapidly to changes in body water status, and is responsible for controlling the rate of water retention by the kidneys. To complicate matters, antidiuretic hormone regulation may be modified by a variety of factors, one of which may be the female sex hormone estrogen (Akaishi & Sakuma, 1990). Early research suggests that the greater body water content in high estrogen states is likely due to changes in both water intake and output in premenopausal women. In addition, fluctuations in antidiuretic hormone parallels those of estrogen throughout the menstrual cycle, and are increased following estrogen administration in postmenopausal women, suggesting that fluid retention is also likely to be increased. Thus, the combination of enhanced fluid intake and retention causes the increase in total body water content during high estrogen states. Some of this excess water is retained in the blood vessels (i.e., in the plasma), leading to plasma volume expansion, which has potent effects on physical performance during heat stress (Stachenfeld & Taylor, 2009). Most people walk every day but it is often overlooked as an exercise activity. Walking is one of the easiest, and cheapest, ways to improve your fitness and increase specific hormones in young individual. It is a light cardiovascular exercise, which means it improves the condition of your heart and lungs (Suter et al., 1994). Chumlea et al concluded that there is inadequate timely information on measured total and extra-cellular water volumes for the population (Chumlea et al., 2007). Distributional body water relationships within the body have been considered fixed, but there was evidence these relationships were affected by the level of fatness, body composition models and to our knowledge, no study has shown the effect of an exercise program on body water in obese and thin women with a mean age of 20 years simultaneously that were performing the same exercise program. The purpose of this study was to investigate whether two months program of closely supervised walking exercise would be beneficial for increasing body water among healthy sedentary obese and thin women.

Material and methods
Forty young untrained girls between the age of 20-25 years (obese n=20, BMI>30 and thin n=20, BMI <20) volunteered to participate in this study. Participants were randomly assigned to two exercises (obese=10, thin=10) and two control (obese=10, thin=10) groups matched by BMI. Written informed consent for all procedures was obtained from all participants prior to entering the study and this study was approved by local Committee of Ethics. The criteria for the invitation were being willing to participate, clinically healthy

Change in data on both exercise and control program. No major change in menstrual status was observed. Forty subjects (100%) completed the training program. The following measurements were made at baseline prior to the start of the exercise program and at after completion of the 2-month training program. Measurements. Body weight and height were recorded and body mass index (BMI) was calculated as weight (kg) divided by height (m) squared. DXA (Lunar DPX-L, software version 1.31, USA) was used to measure each subject's body water, percentage body fat and lean mass. The DXA scans were performed in the Orthopaedic Diagnostic Centre at the National University Hospital, Guilan. In addition, all subjects were weighed every week. Blood samples were collected after an overnight fast (>12 h) in a sitting position and centrifuged at 1500 rpm for 30 minutes at 4°C within 2 h. Serum sample from each participant were stored frozen at -20°C until analyzed. Serum estrogen level was assessed by radioimmunoassay (Amersham Biosciences, Piscataway, NJ, USA) in follicular stage in each subject’s menstrual cycle. The program included warm-up phase for 5 minutes that included stretching exercises, 30 minutes walking at 50-75% of maximum heart rate and cooling-down phase for 5 minutes of stretching, three times a week for 2 months in indoor place. A target heart rate range between 55-70% of age adjusted maximum heart rate intensity was calculated by each walker from her age and walking supine resting heart rate (Swain et al., 1994). Heart rate was measured with an electronic heart rate monitor (Sport Tester PE, Polar Electro, Oy, Finland). The exercise program was accompanied by drinking water in every 10 minutes. Data analysis. The data were analyzed using the SPSS 11.5 for Windows (SPSS, Chicago, IL, USA). Mean and standard deviation (SD) was used as descriptive statistic. Student's t-test was to assess the change in BMI, body weight, serum estrogen and body water before and after the exercise intervention. A significance level of set at p<0.05 was used for all comparisons.

**Results**

Forty subjects (100%) completed the training program. No major change in menstrual status was observed during the study. Table (1) shows the changes in data on both exercise and control groups. There were no significant differences in mean age, height between the groups. There is notable differences between the groups were body weight, BMI in obese and thin groups. Percent body fat and lean mass were affected positively by exercise program and significant change was observed in Serum estrogen and body water in both exercise group (p<0.05-0.001).

**Discussion**

This is the first study to assess the effect of exercise on body water in young women. This difference may be due to the younger age of subjects in our study and the nature of the mechanical load. In our patient a simple 30 minutes of walking exercise at the range of 50-75% maximum heart rate was enough to decreasing the fat mass and increasing lean body weight. “Lean mass” means muscle.“Lean mass,” the researchers conclude, “is the major determinant of body size, providing further evidence that body size is adapted to the dynamic load imposed by muscle force rather than passive loading” by fat. On the other hand Muscle mass able to hold more water weight to fat mass (Thompson et al., 2004). Increase in serum estrogen and total body water in both exercise obese and thin group is good responses to walking program. These mechanisms probably include increasing plasma protein oncotic pressure, differences in peripheral vasoconstriction in active muscles and inactive tissues, and elevated lymph flow. The interaction of these factors provides optimal thermoregulatory and cardiovascular stability. The beneficial effects of hyperhydration and subsequent hypervolemia are manifest in the adaptation of body fluids and electrolytes to exercise training. Thus, with regard to fluid receiving shifts during exercise, training is an effective way to become hyper hydrated and to reduce the dehydration (Convertino, 1987). Stachenfeld et al similarly indicates water retention was the primary contributor to increasing estrogens during endurance exercise. Weinheimer et al (2008) supported that young, physically active women can completely compensate for exercise-induced sweat losses by increasing adequate water intake. Bossingham et al (2005) showed that healthy older adults maintain water input and balance comparable to those of younger adults and have no apparent changes in hydration status. To prevent dehydration, consume plenty of fluids is helpful. In conclusion this study this study demonstrated to 30 minutes walking exercise improved adaptation of body fluids and to exercise training in both obese and thin sedentary women.

**UČINAK AKTIVNOSTI VJEŽBANJA NA TJELESNU VODU KOD SEDENTARNIH MLADIH MRŠAVIH I GOJAZNIH ŽENA**

**Sažetak**
Svrha predstavljenih studije je istraživanje učinka vježbanja hodanjem na tjelesnu vodu u smislu restitucije tjelesne vode i redukcije dehidracije među sedentarnim gojaznim i mršavim ženama. Ukupno 40 netreniranih djevojaka uzrasta između 20 i 25 godina (gojazne n=20, BMI>30 i mršave n=20, BMI <20) dobrovoljno je sudjelovalo u istraživanju. Sudionice su unutar grupa (gojazne, mršave) po slučajnom ključu raspoređene u dvije eksperimentalne (deset gojaznih i deset mršavih) i dvije kontrolne grupe (također po deset gojaznih i deset mršavih) primarno definirane prema BMI indeksu. Korištena je DXA metoda za mjerenje tjelesne vode za svaku ispitanicu, postotak masnog tkiva i suhe mase. Određena je razina serumskog estrogena uz pomoć radioimmunoassay (RIA) metode. Sva sesija vježbe hodanja trajala je 30 minuta 3 dana u tjednu za vrijeme 2 mjeseca, uz intenzitet koji odgovara 50-75 % uzrastu prilagođene maksimalne srčane frekvencije. Postotak masnog tkiva i suhe mase pozitivno je zahvaćen programom vježbanja i značajne promjene su primjerene u Serumskom estrogenu i tjelesnoj void u obje eksperimentalne grupe (p<0.05-0.001). Zaključno, ovo istraživanje je pokazalo da vježba hodanja od 30 minuta povećava adaptaciju tjelesnih tekućina na tjelesni trening kod obje grupe, i gojaznih i mršavih sedentarnih žena.

**Ključne riječi:** vježba hodanja, tjelesna voda, žene, gojazne i mršave
